Discussion

- Dates for the Midterm
- Dates for the Lab

October 2010						
Sunday	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday
3	4	5	6 You are here	7	8	9
10	11	12	13	14	15	16
17	18 Scanner & Parser due	19	20	21	22	23
34	25	26	27	28	29	30
31	1 Lab 2 due (Table gen.)	2	3	4	5	6

The Moral of the Story

- Non-local computation needed lots of supporting rules
- Complex local computation was relatively easy

The Problems

- Copy rules increase cognitive overhead
- Copy rules increase space requirements
 - Need copies of attributes
 - Can use pointers, for even more cognitive overhead
- Result is an attributed tree

(somewhat subtle points)

- Must build the parse tree
- Either search tree for answers or copy them to the root

A good rule of thumb is that the compiler touches all the space it allocates, usually multiple times

Addressing the Problem

If you gave the problem of estimating cycle counts to a competent junior or senior CS major, ...

- Introduce a central repository for facts
- Table of names
 - Field in table for loaded/not loaded state
- Avoids all the copy rules, allocation & storage headaches
- All inter-assignment attribute flow is through table
 - Clean, efficient implementation
 - Good techniques for implementing the table (hashing, § B.3)
 - When it is done, information is in the table!
 - Cures most of the problems

Unfortunately, this design violates the functional paradigm of an AG. Do we care?

The Realist's Alternative

Similar ideas work for topdown parsers...

Ad-hoc syntax-directed translation

- Build on bottom-up, shift-reduce parser
- Associate a snippet of code with each production
- At each reduction, the corresponding snippet runs
- Allowing arbitrary code provides complete flexibility
 - Includes ability to do tasteless & bad things

To make this work

- Need names for attributes of each symbol on lhs & rhs
 - Typically, one attribute passed through parser + arbitrary code (structures, globals, statics, ...)
 - Yacc introduced \$\$, \$1, \$2, ... \$n, left to right
- Need an evaluation scheme
 - Fits nicely into LR(1) parsing algorithm

Reworking the Example

(with load tracking)

```
Block<sub>0</sub>
                        Block<sub>1</sub> Assign
2
                        Assign
3
                   \rightarrow Ident = Expr;
     Assign<sub>0</sub>
                                                                                        This looks cleaner
                                             cost \leftarrow cost + COST(store)
                                                                                           & simpler than
4
                  \rightarrow Expr<sub>1</sub> + Term cost \leftarrow cost + COST(add)
     Expr_0
                                                                                           the AG sol'n!
                        Expr_1 - Term cost \leftarrow cost + COST(sub)
5
6
                        Term
      Term<sub>o</sub>
                   \rightarrow Term<sub>1</sub> * Factor cost \leftarrow cost + COST(mult)
8
                        Term<sub>1</sub> / Factor cost \leftarrow cost + COST(div)
9
                        Factor
10
     Factor
                   \rightarrow (Expr)
11
                        Number
                                               cost \leftarrow cost + COST(loadI)
12
                        Ident
                                               i \leftarrow hash(Ident);
                                               if (Table[i].loaded = false)
                                                   then {
                                                      cost \leftarrow cost + COST(load)
                                                      Table[i].loaded \leftarrow true
```

One missing detail: initializing cost

Reworking the Example

(with load tracking)

```
0 Start Init Block

.5 Init \varepsilon cost \leftarrow 0

1 Block_0 \rightarrow Block_1 Assign

2 | Assign

3 Assign_0 \rightarrow Ident = Expr; cost \leftarrow cost + COST(store)
```

and so on as shown on previous slide...

- Before parser can reach Block, it must reduce Init
- Reduction by Init sets cost to zero

We split the production to create a reduction in the middle — for the sole purpose of hanging an action there. This trick has many uses.

Reworking the Example

(with load tracking)

```
$$ ← $1 + $2
    Block_0 \rightarrow Block_1 Assign
2
                                 $$ ← $1
                    Assign
    Assign<sub>0</sub> \rightarrow Ident = Expr; $$ \( \infty COST(store) + $3$
3
    Expr_0 \rightarrow Expr_1 + Term $$ \leftrightarrow$ 1 + COST(add) + $3
4
                5
                              $$ ← $1
                  Term
6
               \rightarrow Term<sub>1</sub> * Factor $$ \leftarrow $1 + COST(mult) + $3
    Term<sub>o</sub>
                    Term<sub>1</sub> / Factor \$\$ \leftarrow \$1 + COST(div) + \$3
8
9
                    Factor
                                   $$ ← $1
                                        $$ ← $2
10
    Factor
               \rightarrow (Expr)
11
                    Number
                                        \$\$ \leftarrow COST(loadI)
12
                    Ident
                                        i \leftarrow hash(Ident);
                                         if (Table[i].loaded = false)
                                           then {
                                              $$ \leftarrow + COST(load)
                                              Table[i].loaded \leftarrow true
                                            else \$\$ \leftarrow 0
```

This version passes the values through attributes. It avoids the need to initialize "cost"

Example — Assigning Types in Expression Nodes

• Assume typing functions or tables F_+ , F_- , F_\times , and $F_{\dot{+}}$

F×	Int 16	Int 32	Float	Double
Int 16	Int 16	Int 32	Float	Double
Int 32	Int 32	Int 32	Float	Double
Float	Float	Float	Float	Double
Double	Double	Double	Double	Double

1	Goal	\rightarrow	Expr	\$\$ = \$1 ;
2	Expr	\rightarrow	Expr +Term	$$$ = F_{+}($1,$3);$
3			Expr - Term	$$$ = F_{-}($1,$3);$
4			Term	\$\$ = \$1 ;
5	Term	\rightarrow	Term * Factor	$$$ = F_{\times}($1,$3);$
6			Term / Factor	$$$ = F_{\pm}($1,$3);$
7			Factor	\$\$ = \$1 ;
8	Factor	\rightarrow	(Expr)	\$\$ = \$2 ;
9			<u>number</u>	\$\$ = type of num;
10		-	<u>ident</u>	\$\$ = type of ident;

Example — Building an Abstract Syntax Tree

- Assume constructors for each node
- Assume stack holds pointers to nodes
- Assume yacc syntax

```
$$ = $1;
    Goal \rightarrow
                 Expr
    Expr \rightarrow Expr + Term $$ = MakeAddNode($1,$3);
3
                 Expr - Term $$ = MakeSubNode($1,$3);
                             $$ = $1;
                 Term
5
            \rightarrow Term * Factor $$ = MakeMulNode($1,$3);
    Term
                 Term / Factor $$ = MakeDivNode($1,$3);
6
                                 $$ = $1;
                 Factor
                                 $$ = $2;
8
    Factor
            \rightarrow (Expr)
                                 $$ = MakeNumNode(token);
                 number
                                $$ = MakeIdNode(token);
10
                 <u>ident</u>
```

Example — Emitting ILOC

- Assume NextRegister() returns a virtual register name
- Assume Emit() can format assembly code

```
Goal \rightarrow Expr
   Expr \rightarrow Expr + Term
                                   $$ = NextRegister();
                                    Emit(add, $1,$3,$$);
                Expr - Term
                                    $$ = NextRegister();
3
                                    Emit(sub, $1, $3, $$);
4
                                    $$ = $1:
                Term
5
           → Term * Factor
                                    $$ = NextRegister();
   Term
                                    Emit(mult,$1,$3,$$)
                Term / Factor
                                    $$ = NextRegister()'
6
                                    Emit(div, $1, $3, $$);
                                    $$ = $1;
                Factor
```

Comp 412, Fall 2010

Example — Emitting ILOC

- Assume NextRegister() returns a virtual register name
- Assume Emit() can format assembly code
- Assume EmitLoad() handles addressability & gets a value into a register

```
8 Factor \rightarrow (Expr) $$ = $2;

9 | number $$ = NextRegister();

Emit(loadi, Value(lexeme), $$);

10 | ident $$ = NextRegister();

EmitLoad(ident, $$);
```

Reality

Most parsers are based on this ad-hoc style of contextsensitive analysis

Advantages

- Addresses the shortcomings of the AG paradigm
- Efficient, flexible

Disadvantages

- Must write the code with little assistance
- Programmer deals directly with the details

Most parser generators support a yacc-like notation

Typical Uses

- Building a symbol table
 - Enter declaration information as processed
 - At end of declaration syntax, do some post processing
 - Use table to check errors as parsing progresses
- Simple error checking/type checking

assumes table is global

- Define before use \rightarrow lookup on reference
- Dimension, type, ... \rightarrow check as encountered
- Type conformability of expression → bottom-up walk
- Procedure interfaces are harder
 - → Build a representation for parameter list & types
 - → Create list of sites to check
 - → Check offline, or handle the cases for arbitrary orderings

Is This Really "Ad-hoc"?

Relationship between practice and attribute grammars

Similarities

- Both rules & actions associated with productions
- Application order determined by tools, not author
- (Somewhat) abstract names for symbols

Differences

- Actions applied as a unit; not true for AG rules
- Anything goes in ad-hoc actions; AG rules are functional
- AG rules are higher level than ad-hoc actions

Limitations

- Forced to evaluate in a given order: postorder
 - Left to right only
 - Bottom up only
- Implications
 - Declarations before uses
 - Context information cannot be passed down
 - → How do you know what rule you are called from within?
 - → Example: cannot pass bit position from right down
 - Could you use globals?
 - \rightarrow Requires initialization & some re-thinking of the solution
 - Can we rewrite it in a form that is better for the ad-hoc sol'n

Limitations

Can often rewrite the problem to fit S-attributed model

1	Number	\rightarrow	Sign List	\$\$ = \$1 x \$2;
2	Sign	\rightarrow	+	\$\$ = 1;
3		l	-	\$\$ = -1;
4	List ₀	\rightarrow	List ₁ Bit	\$\$ = 2 * \$1 + \$2;
5		I	Bit	\$\$ = \$1 ;
6	Bit	\rightarrow	0	\$\$ = 0 ;
7		I	1	\$\$ = 1

The key step

Of course, you can rewrite the AG in this same S-attributed style

Limitations

Of course, the same scheme works in an attribute grammar

1	Number	\rightarrow	Sign List	Number.val ← Sign.neg x List.val;
2	Sign	\rightarrow	+	Sign.neg ← 1;
3		1	-	Sign.neg ← -1;
4	List _o	\rightarrow	List ₁ Bit	List₀.val ← 2 * List₁.val + Bit.val;
5		1	Bit	List.val ← Bit.val;
6	Bit	\rightarrow	0	Bit.val ← 0;
7		I	1	Bit.val ← 1

We picked the original attribution rules to highlight features of attribute grammars, rather than to show you the most efficient way to compute the answer!

Making Ad-hoc SDT Work

How do we fit this into an LR(1) parser?

```
stack.push(INVALID);
stack.push(s_0);
                                  // initial state
token = scanner.next_token();
loop forever {
     s = stack.top();
     if (ACTION[s,token] == "reduce A \rightarrow \beta") then {
        stack.popnum(2*|\beta|); // pop 2*|\beta| symbols
        s = stack.top();
                         // push A
        stack.push(A);
        stack.push(GOTO[s,A]); // push next state
     else if ( ACTION[s,token] == "shift s;" ) then {
           stack.push(token); stack.push(s_i);
           token \leftarrow scanner.next\_token();
     else if ( ACTION[s,token] == "accept"
                       & token == EOF)
           then break:
     else throw a syntax error;
report success;
```

From an earlier lecture

Augmented LR(1) Skeleton Parser

```
stack.push(INVALID);
stack.push(NULL);
stack.push(s_0);
                                  // initial state
token = scanner.next_token();
loop forever {
     s = stack.top();
     if (ACTION[s,token] == "reduce A \rightarrow \beta") then {
        /* insert case statement here */
        stack.popnum(3*|\beta|); // pop 3*|\beta| symbols
        s = stack.top();
        stack.push(A);
                           // push A
        stack.push(GOTO[s,A]); // push next state
     else if ( ACTION[s,token] == "shift s;" ) then {
           stack.push(token); stack.push(s_i);
           token \leftarrow scanner.next\_token();
     else if ( ACTION[s,token] == "accept"
                      & token == EOF)
           then break:
     else throw a syntax error;
report success;
```

To add yacc-like actions

- Stack 3 items per symbol rather than 2 (3rd is \$\$)
- Add case statement to the reduction processing section
 - → Case switches on production number
 - → Each case clause holds the code snippet for that production
 - → Substitute appropriate names for \$\$, \$1, \$2, ...
- Slight increase in parse time
- 50% increase in stack space

Comp 412, Fall 2010

Making Ad-hoc SDT Work

How do we fit this into an LR(1) parser?

- Need a place to store the attributes
 - Stash them in the stack, along with state and symbol
 - Push three items each time, pop $3 \times |\beta|$ symbols
- Need a naming scheme to access them

Use macros

- \$n translates into stack location (top 3n).
- Need to sequence rule applications
- On every reduce action, perform the action rule
- Add a giant case statement to the parser

Adds a rule evaluation to each reduction

— Usually the code snippets are relatively cheap

Making Ad-hoc SDT Work

What about a rule that must work in mid-production?

- Can transform the grammar
 - Split it into two parts at the point where rule must go
 - Apply the rule on reduction to the appropriate part
- Can also handle reductions on shift actions
 - Add a production to create a reduction
 - \rightarrow Was: fee \rightarrow fum
 - \rightarrow Make it: fee \rightarrow fie \rightarrow fum and tie the action to this new reduction

Together, these let us apply rule at any point in the parse

Alternative Strategy

What if you <u>need</u> to perform actions that do not fit well into the Ad-hoc Syntax-Directed Translation framework?

- Build the abstract syntax tree using SDT
- Perform the actions during one or more treewalks
 - In an OOL, think of this problem as a classic application of the visitor pattern
 - Perform arbitrary computation in treewalk order
 - Make multiple passes if necessary

Again, a competent junior or senior CS major would derive this solution after a couple of minutes of thought.

Summary: Strategies for C-S Analysis

- Attribute Grammars
 - Pros: Formal, powerful, can deal with propagation strategies
 - Cons: Too many copy rules, no global tables, works on parse tree
- Postorder Code Execution
 - Pros: Simple and functional, can be specified in grammar (Yacc) but does not require parse tree
 - Cons: Rigid evaluation order, no context inheritance
- Generalized Tree Walk
 - Pros: Full power and generality, operates on abstract syntax tree (using Visitor pattern)
 - Cons: Requires specific code for each tree node type, more complicated
